## Abstract

Structural heterogeneity of the caprock surface influences both migration patterns and trapping efficiency for CO<sub>2</sub> injected in open saline aquifers. Understanding these mechanisms relies on appropriate modeling tools to simulate CO<sub>2</sub> flow over hundreds of square kilometers and several hundred years during the postinjection period. Vertical equilibrium (VE) models are well suited for this purpose. However, topographical heterogeneity below the scale of model resolution requires upscaling, for example by using traditional flow-based homogenization techniques. This can significantly simplify the geologic model and reduce computational effort while still capturing the relevant physical processes.

In this paper, we identify key structural parameters, such as dominant amplitude and wavelength of the traps, that determine the form of the upscaled constitutive functions. We also compare the strength of these geologic controls on CO<sub>2</sub> migration and trapping to other mechanisms such as capillarity. This allows for a better understanding of the dominant physical processes and their impact on storage security. It also provides intuition on which upscaling approach is best suited for the system of interest.

We apply these concepts to realistic structurally heterogeneous surfaces that have been developed using different geologic depositional models. We show that while amplitude is important for determining the amount of CO<sub>2</sub> trapped, the spacing between the traps, distribution of spillpoint locations, large-scale formation dip angle affect the shape of the

3  
4 function and thus the dynamics of plume migration. We also show for these cases that the  
5 topography characterized by shorter wavelength features is better suited for upscaling, while  
6 the longer wavelength surface can be sufficiently resolved. These results can inform the type  
7 of geological characterization that is required to build the most reliable upscaled models for  
8 large-scale CO<sub>2</sub> migration.

## 20 21 **1. Introduction**

22  
23 2 Geological CO<sub>2</sub> sequestration in saline aquifers has the potential to store large volumes  
24 of anthropogenic CO<sub>2</sub> emissions and mitigate impacts of climate change [1]. The storage  
25 capacity of these aquifers depends primarily on structural, residual and solubility trapping  
26 acting to stabilize the CO<sub>2</sub> plume in the first 1000 years after injection has ceased [2]. The  
27 relative efficiency of these trapping mechanisms will be determined by geologic and fluid  
28 properties [3, 4]. Not only do these parameters affect capacity of a given formation for CO<sub>2</sub>,  
29 but they also impact the long-term risk of leakage out of the formation. Understanding the  
30 impact of these mechanisms on CO<sub>2</sub> migration and trapping in open aquifers is an important  
31 goal of the CO<sub>2</sub> storage community.  
32

33 11 Numerical simulation is an important component for understanding fundamental pro-  
34 cesses occurring in a CO<sub>2</sub> storage site as well as for estimating storage capacity, quantifying  
35 risk and managing storage operations. When applying numerical models to CO<sub>2</sub> migration  
36 and trapping, it is important that the scale of the model matches the scale of the processes  
37 to be simulated [5]. However, CO<sub>2</sub> injection involves large plume footprints that can ex-  
38 tend several kilometers in lateral extent [6] and can potentially migrate up to 100 kilometers  
39 away from the injection well over 100s of years in open dipping aquifers [7]. Meanwhile,  
40 trapping mechanisms such as dissolution by convective mixing [8] and structural trapping in  
41 sub-seismic scale features [9] may occur at the scale of centimeters and meters. These large  
42 discrepancy in temporal and spatial scales need to be modeled simultaneously and presents

3  
4  
5 21 a particular challenge for effective and reliable simulation of long-term evolution of the CO<sub>2</sub>  
6  
7 22 plume.

8  
9 23 Vertical equilibrium (VE) models have emerged in recent years as an alternative to full-  
10  
11 24 physics models for simulating CO<sub>2</sub> injection and migration [5, 10, 11, 12, 13]. These reduced  
12  
13 25 dimension models are effective at capturing the large-scale plume dynamics while coupling  
14  
15 26 in subscale phenomena such as capillary effects [14] and enhanced dissolution by convective  
16  
17 27 mixing [15]. In a recent paper [16], we have explored the utility of flow-based upscaling to  
18  
19 28 capture subscale caprock topography on plume migration and trapping. We showed that up-  
20  
21 29 scaled permeability and relative permeability constitutive functions could be derived through  
22  
23 30 analytical or numerical upscaling that simulate the reduced plume speed and enhanced trap-  
24  
25 31 ping for relatively idealized systems.

26  
27 32 One important aspect of these upscaled constitutive functions is that the shape of the  
28  
29 33 function could be dependent on the type of surface being upscaled. For instance, a sinusoidal  
30  
31 34 surface produces an effective relative permeability that more quickly approaches the function  
32  
33 35 for a flat caprock surface (with no roughness) than a square-wave type of functions. However,  
34  
35 36 these are idealized structures at the limits of real caprocks, and it was not clear how these  
36  
37 37 functions would change for more realistic geological surfaces. In this paper, we explore  
38  
39 38 the impact of different geologic controls on the form of the relative permeability functions.  
40  
41 39 In addition, we develop a set of dimensionless groupings to compare the strength of surface  
42  
43 40 roughness effect compared to the height of capillary fringe, which is another relevant physical  
44  
45 41 phenomenon in CO<sub>2</sub> storage. Finally, we apply these concepts to simulate large-scale plume  
46  
47 42 migration and trapping along realistic geological surfaces.

48  
49 43 The results of this paper increase our understanding of which topographical parame-  
50  
51 44 ters have the most impact on upscaled functions, as well as how best to apply upscaling  
52  
53 45 approaches to different geological settings. If complex geology can be simplified, then com-  
54  
55 46 putational efficiency increases significantly. Faster simulation allows for easier exploration  
56  
57 47 of the parameter space and ultimately a better understanding of the impact of geological  
58  
59 48 uncertainty on CO<sub>2</sub> migration.

33 Figure 1: VE model CO<sub>2</sub> injection and migration with heights of brine, mobile CO<sub>2</sub>, with associated capillary  
34 fringe, residually trapped CO<sub>2</sub>, and region with dissolved CO<sub>2</sub>. Insets show subscale processes that are  
35 implemented into the VE model used in this study, including structural heterogeneity, a capillary fringe, and  
36 convectively-driven CO<sub>2</sub> dissolution. The aquifer may be tilted at a large-scale dip angle  $\theta$  relative to the  
37 horizontal, which may vary in space.  
38  
39

40  
41 The VE model is employed for CO<sub>2</sub> injection into a deep saline aquifer. The model  
42  
43 assumes a two-phase two-component system consisting of a CO<sub>2</sub>-rich phase (subscript  $c$ ) and  
44  
45 a brine-rich phase (subscript  $b$ ). The phases are slightly miscible such that CO<sub>2</sub> can dissolve  
46  
47 into the brine phase and water can dissolve in the CO<sub>2</sub> phase. CO<sub>2</sub> migrates according to  
48  
49 viscous and gravity-dominated forces, while CO<sub>2</sub> trapping occurs in the present model by  
50  
51 structural, residual and solubility mechanisms. Mineral reactions with the host rock have  
52  
53 been neglected.  
54

55  
56 Inherent in the VE model is the assumption that the fluids are segregated vertically so  
57  
58 that capillary and gravity forces are balanced. This means that vertical equilibrium exists  
59  
60 with respect to pressure, and vertical flow can be neglected. As a result, the vertical space

bound by the top and bottom impermeable surfaces,  $\zeta_T(x, y)$  and  $\zeta_B(x, y)$ , respectively, can be subdivided into macroscopic regions bounded by macroscopic interfaces. An example of this vertical structure is depicted in Figure 1. The topmost region is bound below by a dynamic interface  $\zeta_M(x, y, t)$  and is created during the drainage process as  $\text{CO}_2$  displaces brine. This region contains mobile  $\text{CO}_2$  in a fully-drained zone and two-phase  $\text{CO}_2$  and brine in a capillary transition zone, which are separated by an interface  $\zeta_F(x, y, t)$  above which the  $\text{CO}_2$  is at the endpoint saturation with residual brine. When flow reverses and  $\zeta_M$  recedes, brine reimbibes the porespace and traps residual  $\text{CO}_2$  in a region that is bound above by the  $\zeta_M$  interface and below by another dynamic interface  $\zeta_R(x, y, t)$ . The lowest region of fluid is the undrained brine region bound above by  $\zeta_R$  and below by the aquifer bottom at  $\zeta_B$ . The structure is fixed such that  $\zeta_B \leq \zeta_R \leq \zeta_M \leq \zeta_F \leq \zeta_T$

The consequence of capillary-gravity equilibrium is that a well-defined vertical structure in saturation is known. In the simplest case where capillary forces are small, the transition zone can be neglected ( $\zeta_F = \zeta_M$ ) and we obtain the classical sharp-interface model. When capillary forces are strong, the saturation distribution in the relatively large fringe can be obtained from the local capillary pressure curve for the medium. This allows the three-dimensional equations to be integrated over the vertical dimension (perpendicular to the predominant flow direction), resulting in the VE model. The derivation can be performed under different further simplifications, such as a sharp interface or without solubility trapping. See [5, 17] for a full derivation.

2.1. Vertical equilibrium model

Integration of the fine-scale 3D equations leads to a mass conservation equation for the quantity  $M^\alpha$ , which is the mass per unit area of component  $\alpha = c, b$  summed vertically over the  $\text{CO}_2$  and brine fluid phases,

$$\frac{\partial M^\alpha}{\partial t} + \nabla_{\parallel} \cdot \mathbf{F}_{\parallel}^\alpha = Q^\alpha, \quad \alpha = c, b, \tag{1}$$

where  $\mathbf{F}_{\parallel}^\alpha$  is the depth-integrated lateral mass flux of component  $\alpha$  across all phases, and  $Q^\alpha$  is the source/sink term of component mass per area. The lateral direction is assumed to

1  
2  
3  
4  
5 86 be parallel to the large-scale dip angle of the aquifer,  $\theta(x, y)$ , which may vary in space. For  
6  
7 87 convenience, we will omit the  $(\cdot)_{\parallel}$  notation from this point forward.

8  
9 88 The integrated mass fluxes, defined in [15], lead to component fluxes which can be divided  
10  
11 89 into the three macroscopic regions of the aquifer. For example,  $\mathbf{F}^c$  is composed of the sum of  
12  
13 90 CO<sub>2</sub> mass flux with the CO<sub>2</sub> phase ( $\mathbf{F}_c^c$ ) and as a dissolved component with the brine phase  
14  
15 91 ( $\mathbf{F}_b^c$ ),

$$\mathbf{F}_c^c = \int_{\zeta_M}^{\zeta_T} \mathbf{u}_c \rho_c m_c^c dz, \quad (2)$$

$$\mathbf{F}_b^c = \int_{\zeta_R}^{\zeta_M} \mathbf{u}_b \rho_b^{mix} m_b^c dz + \int_{\zeta_B}^{\zeta_R} \mathbf{u}_b \omega \rho_b^{mix} m_b^c dz. \quad (3)$$

16  
17  
18 92  
19  
20  
21  
22 93 Here,  $\rho_c$  and  $\rho_b^{mix}$  are the density of the CO<sub>2</sub> phase and brine phase with dissolved CO<sub>2</sub>,  
23  
24 94 respectively, while the parallel components of fine-scale phase fluxes,  $\mathbf{u}_\beta$ , are given by Darcy's  
25  
26 95 law [18, 15]. Dispersion of dissolved CO<sub>2</sub> is neglected due to the very large spatial scales and  
27  
28 96 relative homogeneity of the system.

29  
30 97 Mass flux in the CO<sub>2</sub> phase depends on the water solubility as a mass fraction,  $m_c^b$ ,  
31  
32 98 where  $m_c^c + m_c^b = 1$ . The flux of dissolved CO<sub>2</sub> is a function of the occurrence of dissolved  
33  
34 99 CO<sub>2</sub> within the residual CO<sub>2</sub> region and below  $\zeta_R$ . The former is governed by equilibrium  
35  
36 100 partitioning given a solubility limit,  $m_b^c$ , while the latter is parameterized by a dynamic  
37  
38 101 term,  $\omega$ , that is a normalized mass fraction parameter,  $\omega$ . More details about upscaled CO<sub>2</sub>  
39  
40 102 dissolution can be found in [15].

41  
42 103 The mass conservation equation is accompanied by a transport equation for dissolved  
43  
44 104 CO<sub>2</sub>,

$$\frac{\partial M_b^c}{\partial t} + \nabla \cdot \mathbf{F}_b^c = C_{\text{diss}}(\omega, \zeta_R), \quad (4)$$

45  
46  
47  
48  
49 105 where  $M_b^c$  is the mass per area of dissolved CO<sub>2</sub> in the brine phase and  $C_{\text{diss}}$  is the up-  
50  
51 106 scaled dissolution rate with units of mass per area per time [15]. Additionally, there is an  
52  
53 107 incompressible conservation equation for the CO<sub>2</sub> fluid phase,

$$H \frac{\partial (\Phi S_c)}{\partial t} + \nabla \cdot \mathbf{U}_c = Q_c, \quad (5)$$

1  
2  
3  
4 108 where  $\Phi$ ,  $S_c$  and  $U_c$  are the depth-averaged porosity, CO<sub>2</sub> saturation, and CO<sub>2</sub> phase flux,  
5  
6 109 respectively, as defined in [16], and  $Q_c$  is the volumetric source/sink of the CO<sub>2</sub> phase.  
7

8 110 The system of equations (1), (4), and (5), consisting of the primary coarse-scale variables  
9  
10 111  $P$ ,  $S_c$  and  $M_b^c$ , can be solved using an IMPES-type strategy whereby the upscaled pressure  
11  
12 112 variable  $P$  is solved implicitly under the assumption of an incompressible system, followed by  
13  
14 113 an explicit solve for  $S_c$  and  $M_b^c$ . A pressure equation is formed by summing (1) and (4) over  
15  
16 114 the phases. The summed equation results in an additional term that accounts for the volume  
17  
18 115 change due to CO<sub>2</sub> dissolution, see [15, 10] for more details. For the transport equations,  
19  
20 116 we consider a splitting type approach, evolving  $S_c$  (Equation (5)), the dissolved CO<sub>2</sub>  $M_b^c$   
21  
22 117 (Equation (4)), and  $\zeta_R$  (by mass balance) in an iterative manner. The spatial domain is  
23  
24 118 discretized and solved numerically using a standard finite-difference approximation.  
25

## 26 119 *2.2. Horizontal upscaling*

27  
28 120 In certain situations, the structural heterogeneity of the caprock may be too fine to be  
29  
30 121 resolved and an upscaled representation of the surface is desired. An additional horizontal  
31  
32 122 averaging of the VE equations presented above can be performed either by analytical or  
33  
34 123 numerical techniques. If the surface fluctuations are periodic within a characteristic length  
35  
36 124 scale  $L$ , such that  $L$  is much smaller than the scale of the domain, then we can apply steady-  
37  
38 125 state flow-based homogenization techniques that have been traditionally used to upscale  
39  
40 126 permeability and relative permeability of heterogeneous media [19, 20].  
41

42 127 The concept of spatial heterogeneity in permeability is applicable here because fluctua-  
43  
44 128 tions in aquifer thickness due to caprock roughness leads to heterogeneity in transmissibility,  
45  
46 129 which is the effective permeability to horizontal flow. In addition, if the physics of the sys-  
47  
48 130 tem is such that CO<sub>2</sub> forms a layer at the top of the aquifer, as discussed in Section 2,  
49  
50 131 the depth-integrated relative permeability will be horizontally heterogeneous as well, even if  
51  
52 132 the CO<sub>2</sub>-brine interface is flat. This heterogeneity will exist despite having a homogeneous  
53  
54 133 porous medium. Horizontal upscaling will result in smoother VE equations, where the effects  
55  
56 134 due to small scale features are transferred to the relative permeability functions. This is in  
57  
58 135 analogy of single phase upscaling where the upscaled equations have a smoother permeability  
59

Figure 2: Caprock roughness at the horizontal fine-scale having spatially varying thickness  $H(x)$  and  $\text{CO}_2$  thickness  $h_c(x)$  within the averaging length  $L$ . The system has a flat bottom  $\zeta_B = 0$  and flat  $\text{CO}_2$ -brine interface. Adapted from [16].

than the fine-scale ones.

The details of the horizontal upscaling can be found in [16]. The objective of upscaling is to replace the varying top boundary  $\zeta_T(x, y)$  with a flat surface over the two-dimensional averaging area with lateral length scale  $L^2$ . This results in an aquifer height that is constant and equal to the average of the thickness at the horizontal fine scale over the averaging length. In one spatial dimension this becomes,

$$\bar{H} = \frac{1}{L} \int_0^L [\zeta_T(x) - \zeta_B(x)] dx. \quad (6)$$

The basic approach is to posit a homogeneous equation at the horizontal coarse scale composed of horizontally averaged quantities. We demonstrate this concept for one-dimensional flow of a single-phase equivalent of the depth-integrated phase flux  $U_\alpha$ . Assuming steady-state flow over the averaging length then the fine-scale single-phase flow equation can be integrated and set equal to the homogeneous equation,

$$U_x = -\frac{\bar{H} \bar{K}_x}{\mu} \frac{\Delta p}{L}, \quad (7)$$

where  $\Delta p$  is the pressure gradient, and  $\mu$  is the viscosity. Horizontally upscaled variables, such as  $\bar{K}_x$ , are indicated with an overbar.

For effective relative permeability  $\bar{K}_\beta$ , additional assumptions are required regarding the saturation at the horizontal fine-scale. Our approach is based on the capillary equilibrium

1  
2  
3  
4  
5 151 assumption [20, 21] that is adapted to the VE rough caprock system and becomes an as-  
6  
7 152 sumption on the CO<sub>2</sub>-brine interface. For small pressure gradients and a horizontal averaging  
8  
9 153 length much smaller than the domain, the CO<sub>2</sub>-brine interface is essentially flat. This means  
10  
11 154 that depth-averaged CO<sub>2</sub> phase saturation  $S_c$  can be fixed within the averaging window dur-  
12  
13 155 ing the upscaling process. Then in a similar manner shown in Equation (7), the two-phase  
14  
15 156 steady-state flow equation is compared with the corresponding homogeneous equation,

$$U_{\beta x} = -\frac{\bar{H} \bar{K}_x \bar{K}_{\beta x}}{\mu_\beta} \frac{\Delta p_\beta}{L}. \quad (8)$$

16  
17  
18  
19  
20 157 The homogeneous equations Equations (7)–(8) can be solved for  $\bar{K}_x$  and  $\bar{K}_{\beta x}$  if a fixed  
21  
22 158 pressure gradient is applied and the steady-state flux is known. For one-dimensional cross-  
23  
24 159 sections and simple two-dimensional surfaces, analytical expressions for the upscaled consti-  
25  
26 160 tutive functions can be derived [16]. However, in general, numerical homogenization is nec-  
27  
28 161 essary. To do this, steady-state flow simulations are performed by resolving the horizontal  
29  
30 162 structure with the VE model described in Section 2.1. Periodic pressure boundary condi-  
31  
32 163 tions are applied with a small pressure gradient in the horizontal direction. For asymmetric  
33  
34 164 surfaces, the simulation must be performed in two dimensions to determine the diagonal and  
35  
36 165 off-diagonal components.

37 166 For relative permeability calculations, the CO<sub>2</sub> is stationary with a vertical saturation  
38  
39 167 distribution fixed according to the local capillary pressure equilibrium. We point out that if  
40  
41 168 flow is faster due to a larger pressure gradient or the caprock surface is tilted, the stationary  
42  
43 169 states for CO<sub>2</sub> saturation in the relative permeability calculations are not trivial and have  
44  
45 170 to be found numerically. The details of the upscaling procedure are described in [16].  
46  
47

### 48 171 **3. Characterization of upscaled constitutive functions**

49  
50  
51 172 In this section we discuss the main characteristics which determine properties of the  
52  
53 173 horizontally upscaled relative permeability functions discussed in Section 2.2. To identify  
54  
55 174 these characteristics, we investigate a set of simplified or idealized caprock surfaces. An  
56  
57 175 important consideration is that these parameters can be calculated for a given storage system  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4  
5 176 given the available data from fine-scale geological models. These parameters can also be  
6  
7 177 estimated for systems where a fine-scale model is not available.

8  
9 178 We propose three sets of geologic parameters to be investigated. The first relates the  
10  
11 179 characteristic width of the structural traps to the distance between each trap. The second  
12  
13 180 relates the dominant wavelength of the structures, wide and shallow versus narrow and  
14  
15 181 steep, and their amplitude, large versus small trapping volumes, to the effect of gravity due  
16  
17 182 to aquifer tilt. The third takes into account surface effects, in particular the asymmetry of  
18  
19 183 the surface and two-dimensional variation in spillpoint depths. The first two analyses can  
20  
21 184 be performed on a one-dimensional surface, where the caprock is represented by a line, while  
22  
23 185 the last must be solved numerically on a two-dimensional surface. We then compare the  
24  
25 186 upscaled curves to the CO<sub>2</sub> relative permeability curve for a flat tilted surface (representing  
26  
27 187 a locally smooth caprock), which is a linear function between zero and unity. This surface  
28  
29 188 is referred to as a “flat” caprock from this point forward.

30  
31 189 All numerical experiments were performed using a sharp-interface assumption with zero  
32  
33 190 brine saturation under VE conditions. It should be noted that the VE assumption is valid  
34  
35 191 for rough surfaces as long as the amplitude is much smaller than the wavelength.

### 36 192 *3.1. Trapping volume and roughness*

37  
38 193 We have seen that the shape of the CO<sub>2</sub> relative permeability curve in previous work [16]  
39  
40 194 is clearly a function of the volume of CO<sub>2</sub> that can be structurally trapped, called *structural*  
41  
42 195 *residual saturation* because CO<sub>2</sub> must exceed a certain thickness before flow can occur in  
43  
44 196 the upscaled sense. The potential trapping volume can be estimated from the amplitude  
45  
46 197 of the structural features or from other simple trapping analyses [9]. Here, we refer to the  
47  
48 198 amplitude ratio  $a$  as the amplitude scaled by the aquifer thickness,

$$49

60  
61  
62  
63  
64  
65$$
$$a = \frac{A}{H}. \quad (9)$$

199 Also, we have observed previously that different structures give varying degrees of roughness  
200 and impact the overall shape of the relative permeability function even when the trapping  
201 capacity is the same. A rougher surface means that CO<sub>2</sub> flow is slower and requires a greater

202 plume thickness before the impact of the roughness becomes negligible, in which case CO<sub>2</sub>  
203 migration becomes similar to flow along a smoother caprock with only buoyancy due to  
204 large-scale dip as the dominant flow mechanism.

205 We take the specific example of an oscillating square wave, which was found to be the  
206 roughest surface compared to other structures for the same amplitude ratio [16]. Because  
207 the system is one-dimensional, the permeability and relative permeability can be derived by  
208 taking the harmonic average of the fine-scale quantities across the horizontal dimension, as  
209 described in [16]. The analytical permeabilities for a square and rectangular topographies  
210 are given in Table 1. The harmonic average is independent of wavelength, which is due to  
211 the single wave structure, but the amplitude ratio and other structural parameters impact  
212 the formula. For the rectangular wave, two relevant parameters are the length scales  $l_1$  and  
213  $l_2$  that are associated with the distance between the structures and their width, respectively.  
214 The general case is a rectangle, such that  $l_1 \neq l_2$ . We can compute the ratio of these lengths  
215 as  $f_r = l_1 / (l_1 + l_2)$ , and compare different ratios for a given trapped volume to determine  
216 the impact of  $f_r$  on surface roughness. Given  $f_r$ , we can then derive the resulting formula  
217 for the rectangle, also in Table 1, which reduces to a square for  $f_r = 0.5$ .

218 The shape of the rectangle curves for different values of  $f_r$ , shown in Figure 3, varies  
219 between two limits. The limit when  $f_r \rightarrow 0$  results in a linear function from  $\bar{S} = a$  to unity.  
220 This case consists of structures that extend over the entire surface with an infinitesimally  
221 small distance separating them, which happens to correspond to the accretion layer model  
222 (AM) derived in [16]. The upper limit when  $f_r \rightarrow 1$  results in a relative permeability that  
223 jumps from zero to the flat caprock curve at  $\bar{S} = a$ . This phenomenon occurs because, as  
224 the traps approach an infinitely small width of some volume, the surface essentially becomes  
225 identical to the reference flat caprock but with periodic instantaneous sinks. Thus, once the  
226 infinitely thin traps are filled, the relative permeability jumps from zero (no flow) to the  
227 reference flat surface curve (flow) because the traps do not affect flow once they are filled.

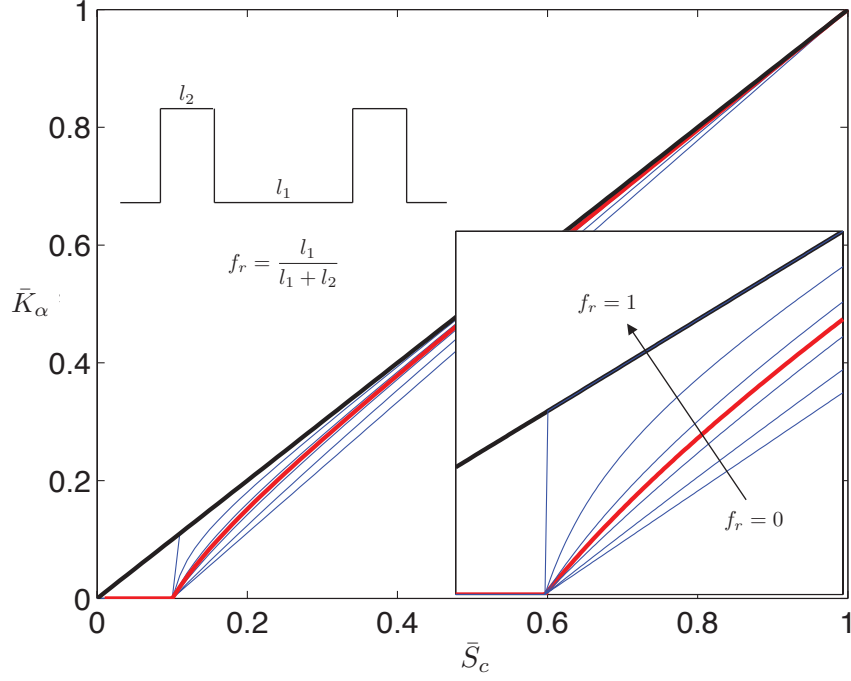

Figure 3: Upscaled CO<sub>2</sub> relative permeability curves for the rectangle surfaces for different values of roughness ratio  $f_r$ . The black line is the reference case—a linear relative permeability curve for a flat caprock—and the red is the square case with  $f_r = 0.5$ .

Table 1: Summary of effective permeability and relative permeability functions for different functional forms of caprock topography, where  $\hat{h}_b = \bar{h}_b/\bar{H}$  and  $\hat{h}_b \leq a$ .

Topography	$\bar{K}$	$\bar{K}_b$	$\bar{K}_c$
flat	$K$	$k_b^0 \hat{h}_b$	$k_c^r (1 - \hat{h}_b)$
square	$K (1 - a^2)$	$k_b^0 \hat{h}_b$	$k_c^r \frac{(1 - \hat{h}_b)^2 - a^2}{(1 - \hat{h}_b)(1 - a^2)}$
rectangle	$K \left( \frac{f_r}{(1-a)+a/f_r} + \frac{1-f_r}{1-a} \right)^{-1}$	$k_b^0 \hat{h}_b$	$k_c^r \frac{\frac{f_r}{(1-a)+a/f_r} + \frac{1-f_r}{1-a}}{\frac{f_r}{(1-\hat{h}_b-a)+a/f_r} + \frac{1-f_r}{1-\hat{h}_b-a}}$

1  
2  
3  
4  
5 228 *3.2. Effect of caprock tilt and wavelength*

6  
7 229 In the one-dimensional examples of sinusoidal waves studied in [16], the large-scale dip  
8  
9 230 of the surface was assumed to be nearly horizontal. This simplification implies several  
10  
11 231 things. First, the trapped volume of a horizontal surface is maximized for a given amplitude  
12  
13 232 compared with the tilted surface. This occurs because the spillpoints are raised relative to  
14  
15 233 the horizontal, allowing CO<sub>2</sub> to flow and thus reducing trapping capacity. Secondly, the  
16  
17 234 upscaled relative permeability is independent of wavelength,  $\lambda$ , when the surface has zero  
18  
19 235 dip angle. Additionally, there is a sharp transition in the CO<sub>2</sub> flow characteristics from  
20  
21 236 the non-flowing to the flowing case, meaning that once CO<sub>2</sub> thickness exceeds the residual  
22  
23 237 saturation the flowing CO<sub>2</sub> very quickly becomes flow along a smooth flat surface with only  
24  
25 238 a small additional increase in CO<sub>2</sub> saturation.

26  
27 239 We investigate the impact of large-scale tilt of the caprock, measured as the angle  $\theta$  from  
28  
29 240 the horizontal, by varying the tilt for a given sinusoidal amplitude and wavelength. Figure  
30  
31 241 5 shows that as  $\theta$  increases, the residual saturation decreases, which is as expected. An  
32  
33 242 additional striking qualitative change is a smoother transition from non-flowing to flowing  
34  
35 243 regime with increasing  $\theta$ . This result can be attributed to the extent of CO<sub>2</sub> flow along the  
36  
37 244 “dry region,” which is defined as the portion of the caprock under which no CO<sub>2</sub> accumulates  
38  
39 245 or is trapped. At the limit when  $\theta = 0$ , the dry region is very small and therefore does not  
40  
41 246 impact the flow once the residual saturation is exceeded. However, with a tilted surface, the  
42  
43 247 dry region is larger and grows in size with increasing tilt. This means that CO<sub>2</sub> must flow  
44  
45 248 along the dry region, which causes more resistance than the horizontal case. The size of  
46  
47 249 the dry region increases with increasing wavelength and decreasing amplitude, all else being  
48  
49 250 equal.

50  
51 251 *3.3. Two-dimensional surface effects*

52  
53 252 Above, we saw that increasing the tilt of the caprock surface in one-dimensional can  
54  
55 253 introduce a smoother transition from the non-flowing to the flowing regime. A similar  
56  
57 254 phenomena can occur due to varying depths of local minima (spillpoints) within the two-  
58  
59 255 dimensional averaging window, as shown schematically in Figure 4. In the general case, CO<sub>2</sub>

256 will exceed only the shallowest spillpoint first, initiating flow along only a small portion of  
257 the surface. As CO<sub>2</sub> thickness increases, the flowing surface gradually increases until the  
258 deepest spillpoint is exceeded. This impact can occur even for a horizontal surface ( $\theta = 0$ ),  
259 however it is solely a two-dimensional phenomenon since in the one-dimensional case CO<sub>2</sub>  
260 cannot flow until exceeding the deepest spillpoint.

261 Two scenarios were tested, one with constant and the other with varying spillpoint depth,  
262 as shown in Figure 6. The upscaled relative permeability curves show that the varying case  
263 leads to lower structural residual CO<sub>2</sub> saturation as flow is initiated earlier along the shal-  
264 lowest spillpoint compared to the constant case. We see that both the constant and varying  
265 case lead to anisotropic relative permeability tensors due to asymmetry of the surfaces,  
266 which leads to different flow characteristics in each dimension even in the constant case.  
267 The varying spillpoint depths can be an additional source of anisotropy. A perfectly sym-  
268 metric surface (see [16]) will reduce to scalar relative permeability functions. And finally, we  
269 observe a smoother transition from non-flowing to fully flowing CO<sub>2</sub> in the varying case (for  
270 flow in the  $x$  direction), which implies a gradual increase in CO<sub>2</sub> relative permeability from  
271 the point of flow initiation until meeting the sharper curve for the constant case.

#### 272 4. Application to realistic caprock surfaces

273 The insights obtained from the analysis in Section 3 can aid in characterizing the topogra-  
274 phy of more realistic caprock surfaces. This involves applying the numerical homogenization  
275 techniques described previously to upscale permeability and relative permeability functions.  
276 Additionally, flow simulations on the upscaled surface can be compared to simulations with  
277 the resolved surface to determine the reliability of the upscaling approach. Finally, we assess  
278 the relative importance of structural heterogeneity compared to a capillary fringe, another  
279 relevant process, through flow simulation on the resolved surface.

##### 280 4.1. Description of caprock

281 Two heterogeneous caprock surfaces were compared, each based on datasets developed  
282 for the IGeMS project (<http://www.nr.no/IGEMS>). These large-scale synthetic surfaces (30

Figure 6: The upper row shows the test case surfaces—the left is a varying spillpoint case while the right can be seen as a constant case. The lower panel shows the relative permeability of CO<sub>2</sub> for the two surfaces in both the  $x$  and  $y$  directions (the inset focuses on the CO<sub>2</sub> curve at low CO<sub>2</sub> saturation). The red line is the constant case and the blue line is the varying case.

Table 2: Heterogeneous parameters for the OSS and FMM caprock surfaces.

Parameter	OSS	FMM
Amplitude	<20m	1–10 m
Width	2–4 km	10–300 m
Spacing	2–4 km	40–300 m
Total Trapped Volume	0.26 km <sup>3</sup>	0.85 km <sup>3</sup>

283  $\times 60$  km) were created to represent realistic sandstone storage formations underneath an  
 284 impermeable caprock that has a shallow 1% dip in one direction. The geological features of  
 285 the caprock surfaces modeled here are based on the buried offshore sand ridges (OSS) and  
 286 buried beach ridges in a flooded marginal marine setting (FMM). Although many realizations  
 287 of each geologic setting were created in the original IGEMS study, only one realization of  
 288 each of the OSS and FMM surfaces were used in this paper. More details can be found  
 289 in [22] and the original datasets are available online at the project website. A flat caprock  
 290 surface with the same large-scale attributes as the heterogeneous surfaces (domain size and  
 291 tilt) was also tested as a reference for comparison.

292 The OSS surface consists of relatively large, kilometer-scale structures that are spaced  
 293 a few kilometers apart. In contrast, the FFM surface has much narrower meter-scale struc-  
 294 tures that are spaced close together. In both cases, the elliptical structures are oriented  
 295 perpendicular to the dip direction. The orientation is dependent on the geologic uplift in  
 296 relation to the depositional environment, and therefore a parallel orientation is equally pos-  
 297 sible. However, we chose the perpendicular orientation because it produces the maximum  
 298 trapping potential, which is particularly relevant for the OSS case. Based on the analysis in  
 299 the previous section, relevant parameters are listed in Table 2.

300 A series of resolved simulations were performed with the two heterogeneous surfaces and  
 301 a flat surface. The grid resolution is varied throughout the domain such that the finest  
 302 resolution of 100 m  $\times$  100 m occurs within the region where CO<sub>2</sub> is flowing, with coarser  
 303 resolution towards the lateral boundaries ( $y = 0$  km and  $y = 30$  km). CO<sub>2</sub> was injected at a  
 304 rate of 4 Mt/yr for 50 years through a well located at  $x = 15$  km and  $y = 15$  km. The first

Figure 7: Heterogeneous caprock surfaces for a tilting saline aquifer (1%) created under two different depositional scenarios: buried offshore sand ridges (OSS) on left, and flooded marginal marine (FMM) on right.

set of simulations assumed a sharp interface (SI), representing an aquifer where the capillary fringe is small compared to aquifer thickness and can be neglected. Additional simulations were performed with a relatively large capillary fringe (CF) to explore the parameter space. All simulations allowed for dissolution due to equilibrium partitioning in residual brine and brine in contact with residual  $\text{CO}_2$  but no dissolution due to convective mixing ( $C_{\text{diss}} = 0$ ). The capillary-saturation function employed here is a standard Brooks-Corey function with exponent  $m = -1/2$  and coefficient  $P_0$ . The relative permeability function is also Brooks-Corey with exponent  $n = 3$ . A summary of the parameters can be found in Table 3.

Summarizing the resolved simulation results, we see the impact of topography on the plume migration and the distribution of trapped mass Figures 8 and 9. The OSS surface large individual traps collect significant amounts of  $\text{CO}_2$ , but spread over a greater area than in the FMM case. The capillary fringe also impacts the speed of the plume since the leading edge of the plume is comprised predominantly of low  $\text{CO}_2$  saturations that lead to a lower average relative permeability than the SI case. It should be noted that the CF simulations result in less  $\text{CO}_2$  stored in each of the structural traps because the capillary fringe leads to a lower average saturation for a given  $\text{CO}_2$  plume thickness, defined as the bottom of the mobile  $\text{CO}_2$  region  $\zeta_M$ , particularly at small  $\text{CO}_2$  plume thickness values.

Brine endpoint permeability	0.54	–
Brine solubility	0	% mass
Capillary coefficient, $P_0$	0 (SI)/0.2 (CF)	bar

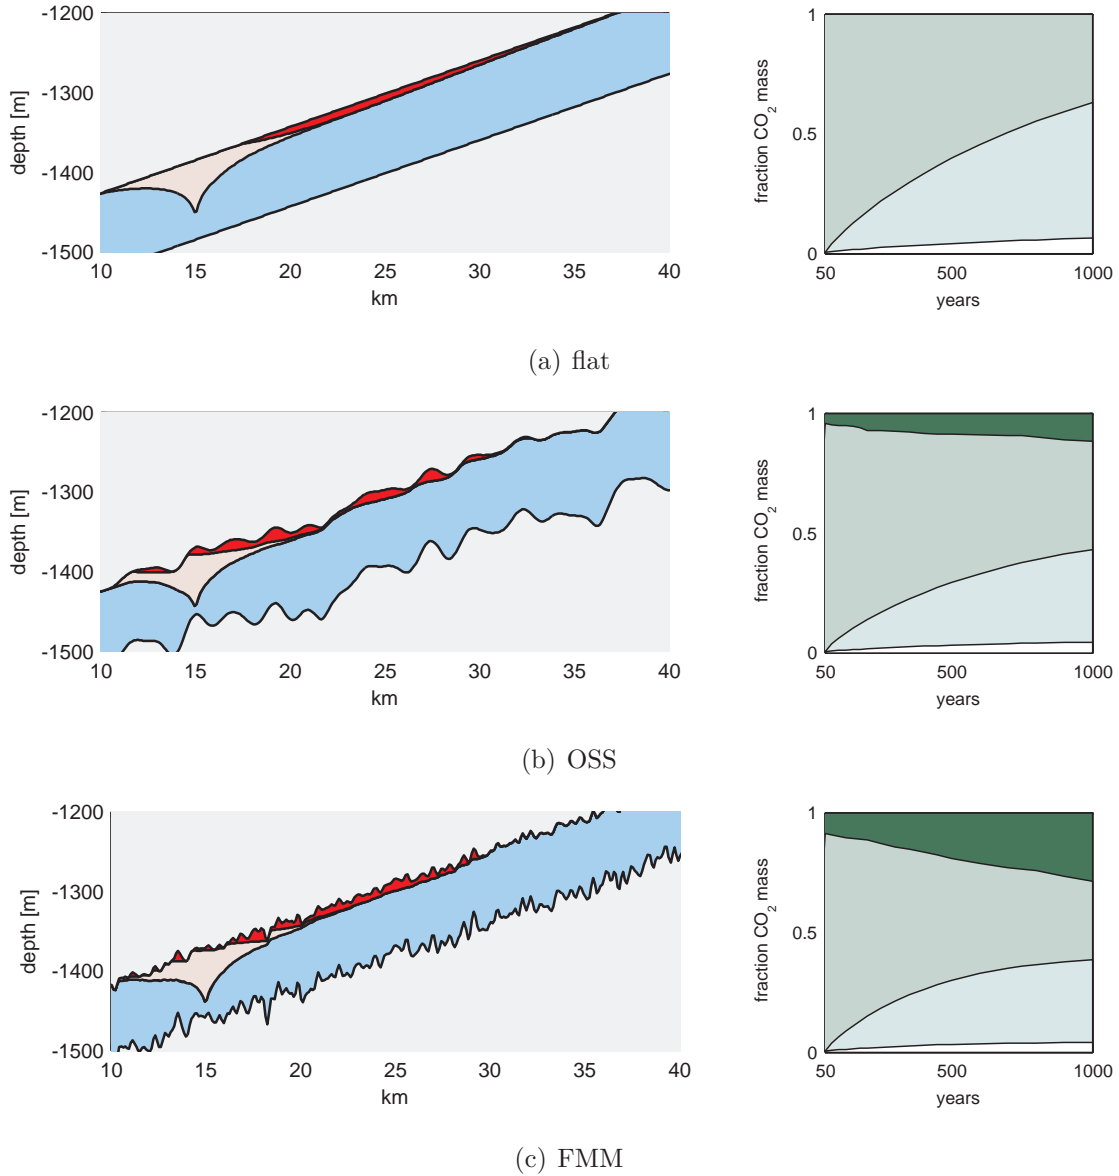

Figure 8: Results from the sharp-interface resolved simulations (SI) depicted along cross-sections (at  $y = 15\text{km}$ ) of the flat (top), OSS (middle), and FMM (bottom) aquifer models. Dark red shaded area is mobile CO<sub>2</sub> region and light red shaded area is region with residually trapped CO<sub>2</sub>. Right panels show temporal evolution of distributed CO<sub>2</sub> mass (fraction of total injected) over 1000 years. From top to bottom (dark to light) are structurally trapped CO<sub>2</sub>, free CO<sub>2</sub> phase, residual CO<sub>2</sub>, and dissolved CO<sub>2</sub>.

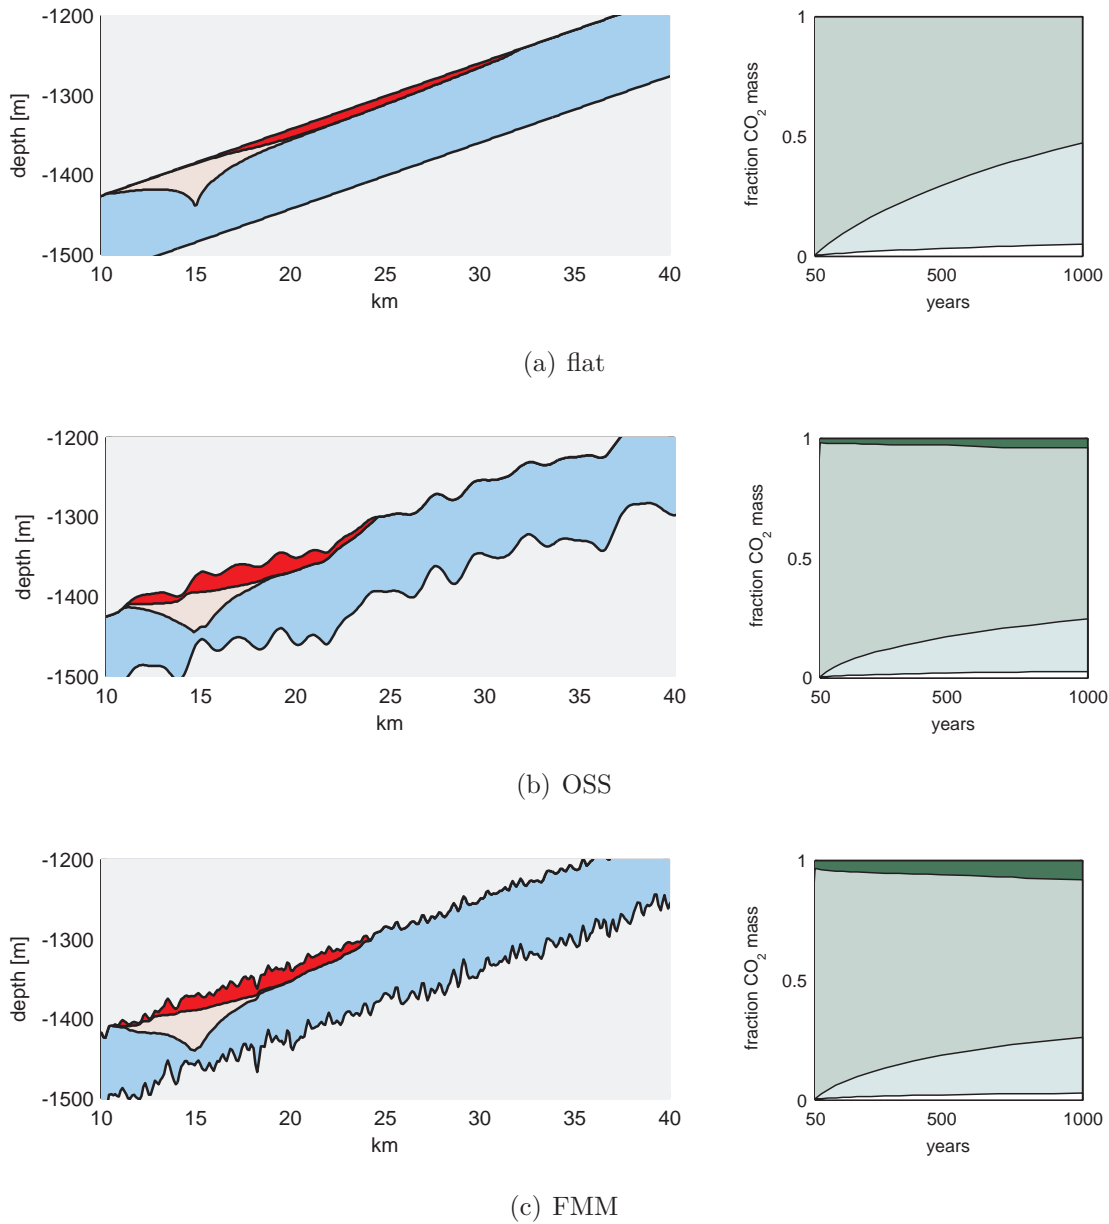

Figure 9: Results from resolved simulations with capillary fringe (CF) depicted along cross-sections (at  $y = 15\text{km}$ ) of the flat (top), OSS (middle), and FMM (bottom) aquifer models. Dark red shaded area is mobile  $\text{CO}_2$  region and light red shaded area is region with residually trapped  $\text{CO}_2$ . Right panels show temporal evolution of distributed  $\text{CO}_2$  mass (fraction of total injected) over 1000 years. From top to bottom (dark to light) are structurally trapped  $\text{CO}_2$ , free  $\text{CO}_2$  phase, residual  $\text{CO}_2$ , and dissolved  $\text{CO}_2$ .

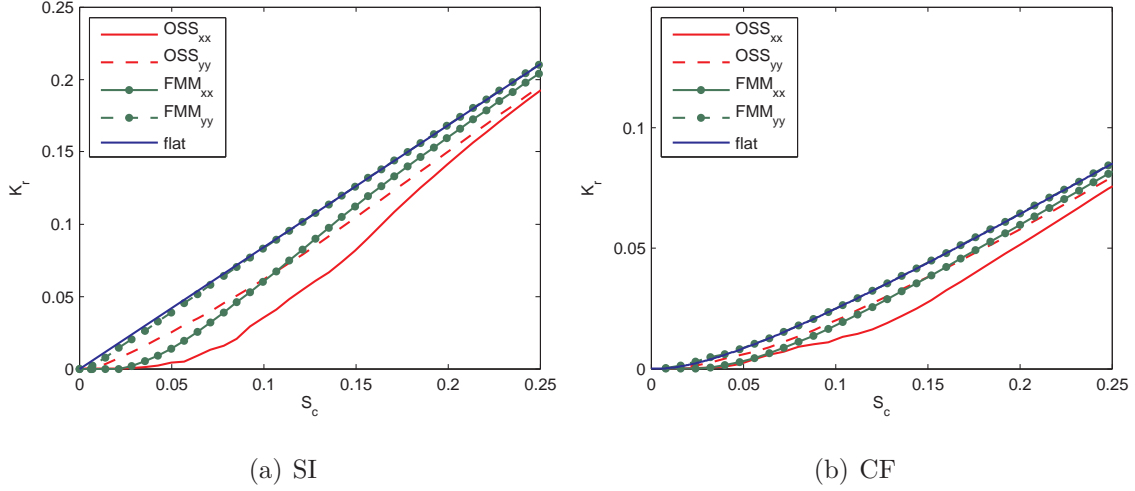

Figure 10: Upscaled CO<sub>2</sub> relative permeability curves for the SI (left) and CF (right) fluid properties on the OSS and FMM surfaces, compared with the flat caprock curves for both SI and CF fluid properties.

#### 4.2. Upscaling

The heterogeneous surfaces were upscaled using numerical flow-based upscaling to determine  $\bar{\mathbf{K}}_c$  as a function of  $\bar{S}_c$  using Equation (8). The steady-state simulations were performed on a subsection equal to one-third of the domain for of each surface, which was done in order to capture several wavelengths of the structures. The CO<sub>2</sub> relative permeability was upscaled for both the sharp interface (SI) and capillary fringe (CF) cases, which are shown in Figure 10. The brine relative permeability is assumed to be unchanged from the vertically upscaled function such that  $\bar{\mathbf{K}}_b = \mathbf{K}_b$ .

Due to the asymmetric nature of the FMM and OSS surfaces, the upscaling results in tensorial relative permeability for both cases. The  $xx$  component is more significantly changed from the reference surface, which is due to the long dimension of the structures being oriented perpendicular to the  $x$  direction in both cases. The grid is aligned to the structures, so therefore the off-diagonal component is negligible compared to the others. The OSS structure leads to a more gradual increasing of CO<sub>2</sub> relative permeability with  $\bar{S}_c$  than the FMM case, with smaller  $\bar{\mathbf{K}}_c$  for all values of  $\bar{S}_c < 0.25$ . This shows the OSS traps impact the flow of CO<sub>2</sub> much more after the structural residual saturation has been exceeded than the FMM surface.

339 To perform upscaled simulations of the SI and CF cases, the upscaled relative perme-  
340 ability functions in Figure 10 were employed uniformly in an “effective aquifer”–defined as  
341 having a flat caprock surface and constant 100-m thickness. The grid resolution was in-  
342 creased to 400 m, which was uniform across the domain. The resulting plume migration  
343 after 600 years shows good comparison to a varying degree with the resolved simulations  
344 (plan view in Figure 11). For the SI simulations, the OSS upscaled model underestimates  
345 the updip extent of the plume, while the FMM upscaled results give a better comparison.  
346 For the CF cases, the OSS upscaled model compares better to the resolved simulations than  
347 the FMM, which overestimates plume speed in this case. The better comparison in the CF  
348 simulations implies that a capillary fringe has more impact than the OSS and FMM struc-  
349 tural effects. Despite the discrepancies seen in Figure 11, the upscaled simulations result  
350 in a better representation of plume migration than the reference flat caprock simulations  
351 performed with no upscaling (top panels).

352 As expected, the upscaled models are not able to capture the local distribution of trapped  
353 CO<sub>2</sub> over the caprock surface. However, the upscaling is able to capture the large-scale  
354 features of the plume to different degrees. The OSS case, which consists of large traps at a  
355 similar length scale to the CO<sub>2</sub> plume, leads to a larger discrepancy between the upscaled  
356 and resolved simulations. The updip extent of the plume is much smaller, though the  
357 lateral width of the plume is similar. The difference occurs because the relative permeability  
358 functions are upscaled over a large portion of the OSS surface, assuming the impact of the  
359 structures is “homogeneous” over the entire surface. However, it is clear in the resolved  
360 simulations that the impact of structures is more heterogeneously, or sparsely, distributed  
361 as CO<sub>2</sub> migrates along the surface. The FMM case, with much smaller width traps than  
362 the plume has greater homogeneity compared to the scale of the plume, thus the impact  
363 is captured better in the upscaled relative permeability functions and results therefore in a  
364 more consistent match with the resolved simulations. However, we find that the upscaled  
365 models capture the integrated amount of trapped CO<sub>2</sub> over the whole domain reasonably  
366 well, as shown in the top panels of Figure 12.

367 Also in Figure 12, we find the upscaled models have mixed results when comparing  
368 upslope extent and plume footprint over the simulated period. In the SI cases, the FMM  
369 upscaled simulations are able to capture the impact of topography most effectively, especially  
370 with regard to plume footprint. On the other hand, the OSS is unable to capture plume dy-  
371 namics with much accuracy. The CF simulations had better comparisons overall between the  
372 upscaled and resolved cases, with some persistent overestimation. Despite this discrepancy,  
373 the rate of increase at late time is nearly the same as the resolved CF simulations.

### 374 5. Dimensionless groupings

375 In this paper we have identified several important topographical parameters that impact  
376 upscaled models of CO<sub>2</sub> migration and trapping in structurally heterogeneous systems. First,  
377 we investigated idealized topographies to gain insight into the effect of heterogeneity on up-  
378 scaled relative permeability functions. This analysis leads to simple dimensionless groupings  
379 that can be used to estimate the impact of structural heterogeneity that can be expected  
380 for different surfaces. The five groupings are summarized in Table 4, which include three  
381 new groupings proposed here along with the  $a$  and  $f_c$  groupings proposed previously [16, 23].  
382 Also included in the table are groupings that compare another important physical process,  
383 the capillary fringe, to the influence of structure. These will be discussed further here.

384 The first key topographical parameter identified in previous work is trapped volume,  
385 described by the amplitude ratio  $a$ . A larger amplitude ratio means more trapping and a  
386 slower migration speed. While amplitude is important, it only determines the structural  
387 residual saturation that must be exceeded for CO<sub>2</sub> to flow freely across the surface. Once  
388 CO<sub>2</sub> is flowing, the shape of the upscaled relative permeability curve is determined by other  
389 structural characteristics that contribute to surface roughness. We identified three dimen-  
390 sionless groups that determine roughness—the relief, tilt and spillpoint ratios—which lead to  
391 different impacts on the relative permeability curve.

392 The relief ratio ( $f_r$ ) compares the distances between traps to their width for a fixed  
393 trapped volume. As the distance decreases from one trap to another, the width of the traps  
394 increases in proportion and  $f_r$  decreases, thereby increasing roughness. This means that

Table 4: Characteristic groupings of geological and fluid parameters that impact plume migration and trapping along a rough caprock surface. The groupings are quantified for the OSS and FMM surfaces given the parameters listed in Tables 2 and 3

Topography Characteristics	Grouping	OSS	FMM
Amplitude Ratio	$a = \frac{A}{\bar{H}}$	0.2	0.1
Relief Ratio	$f_r = \frac{l_1}{l_1 + l_2}$	0.5	0.8
Tilt-Wavelength Ratio	$f_t = \frac{\lambda}{A} \tan \theta$	1	0.04
Spillpoint Ratio	$f_s = \frac{\max \zeta_T}{\min \zeta_T}$	1.5	1
Capillary Ratio	$f_c = \frac{p_c^*}{a\bar{H}\Delta\rho g \cos \theta}$	1.42	2.8

comparing two systems that have the same overall trapping capacity, the one with low-relief, wider features that blend together will have a greater reduction on plume migration speed than a system with more pronounced high-relief features spaced far apart.

The tilt-wavelength ratio ( $f_t$ ) relates wavelength ( $\lambda$ ) to the dip angle ( $\theta$ ) of the aquifer. This ratio can be used to compare the roughness of two surfaces with identical trapping capacity and dip angle, where a lower  $f_t$  indicates a lower roughness. The topography with a smallest dominant wavelength results in the smallest roughness because the curvature of the CO<sub>2</sub> relative permeability function is decreased at low wavelength. A reduced curvature implies higher upscaled CO<sub>2</sub> relative permeability for the same plume thickness. The roughness also differs between two surfaces with the same wavelength but a different tilt angle. In this case, the increased tilt angle increases roughness while also decreasing the trapping capacity of the surface. And finally, the tilt-wavelength ratio indicates that two horizontal surfaces ( $\theta = 0$ ), which only differ in wavelength, will have the same relative permeability functions.

The fourth grouping, spillpoint ratio ( $f_s$ ), compares the distribution of spillpoint depths

410 over the averaging area and can only be identified for two-dimensional surfaces. A large ratio  
411 means the difference between the shallowest and deepest spillpoint is large and the roughness  
412 of the surface is greater. The roughness is increased because although CO<sub>2</sub> flow is initiated  
413 over the shallow spillpoints early, the transition to a fully flowing CO<sub>2</sub> plume (reaching be-  
414 yond the deepest spillpoint) is slow. Therefore, the caprock continues to impact plume speed  
415 even for a smaller trapped volume overall. This affects the upscaled relative permeability  
416 function by creating a smoother transition from non-flowing to the flowing regime compared  
417 to a case with all spillpoints at the same level. Different spillpoint distributions will lead to  
418 different flow regimes and corresponding upscaled relative permeability curves.

419 Given this set of structural parameter groupings, it is necessary to evaluate their utility  
420 for understanding CO<sub>2</sub> migration along more realistic heterogeneous surfaces. To do this,  
421 simulations were performed along two surfaces, OSS and FMM, that were inspired by dif-  
422 ferent depositional settings common in sedimentary basins. We can compare the quantified  
423 dimensionless groupings for each surface (given in Table 4) with the respective upscaled rel-  
424 ative permeability curves and simulation results. It should be noted that there are several  
425 impacts occurring simultaneously, so making exact comparisons with dimensionless group-  
426 ings is difficult. Regardless, some interesting observations can be made.

427 In the upscaled relative permeability functions seen in Figure 10, the OSS curve indicated  
428 a rougher surface with little trapping. The quantified values in Table 4 show that the OSS  
429 surface has a higher amplitude ratio, which would normally indicate a larger structural  
430 residual saturation than the FMM curve. However, the total trapped volume for the OSS  
431 over the entire surface is lower than the FMM (Table 2), leading to flow starting at a lower  
432 average CO<sub>2</sub> saturation than the FMM curves.

433 This discrepancy indicates that some other structural factors are dominant. For example,  
434 the FMM relief ratio is higher than the OSS, indicating that the OSS is rougher, but the  
435 values do not differ greatly. A similar conclusion can be drawn from a comparison of  $f_s$ .  
436 On the other hand, the value of  $f_t$  for OSS is nearly two orders of magnitude greater than  
437 the FMM. This is because the geologic parameters (width and spacing) given for the OSS

438 in Table 2 result in kilometer-scale wavelength compared with 100 meters for the FMM.  
439 Therefore, we conclude that the moderate tilt combined with a long wavelength has the most  
440 significant impact on the increased curvature of OSS relative permeability curves compared  
441 to the FMM. The larger OSS wavelength can also explain a decreased trapping (because of  
442 the tilted surface) despite having a larger amplitude.

443 The flow simulations on the OSS and FMM surfaces are also valuable for comparing the  
444 relative importance of structural effects to other processes that impact CO<sub>2</sub> flow over large  
445 scales. For example, in Section 4, we performed simulations with a relatively large capillary  
446 fringe. Similar to previous work [23], we observed that a capillary fringe also slows the plume  
447 migration, and becomes important as the length scale of the fringe increases compared with  
448 the vertical dimension of the aquifer. The fringe also competes with structural roughness  
449 in slowing the plume migration, i.e. the relative impact of the structural effects increases  
450 as the capillary length scale decreases and vice versa. The capillary fringe ratio  $f_c$  gives  
451 an indication of the relative strength of these effects. As the capillary ratio decreases, the  
452 structures dominate the flow. Conversely, capillarity will dominate if the fringe is much  
453 larger than the dominant amplitude of the structures. We see that the OSS has the smaller  
454 capillary ratio, but the upscaled relative permeability curves and simulation results indicate  
455 that a sufficiently large capillary fringe will overwhelm the structural heterogeneity for both  
456 the OSS and FMM caprock surfaces.

## 457 6. Upscaling considerations

458 This study gives valuable insight into the effectiveness of upscaled models under realistic  
459 geological settings and fluid properties. By comparing the length scale of the plume to that  
460 of the main structures, we can evaluate the conditions under which upscaling is a practical  
461 means of simplifying the system while still capturing the CO<sub>2</sub> plume dynamics and trapping.

462 For example, we observed that the upscaled OSS model performed poorly for all aspects  
463 of the SI simulation, the scenario for which structural effects are most important. The  
464 relatively poor representation of the resolved model occurred because the upscaled functions  
465 were employed in grid blocks whose size was much smaller (400 m) than the width of the

466 structural features (2000 m). This led to trapping of CO<sub>2</sub> that was correct on average, but  
467 did not capture the large-scale distribution of trapped CO<sub>2</sub> as compared with the resolved  
468 model. Also, plume migration speed was impacted homogeneously over the entire upscaled  
469 surface, even though the traps were more sparsely spaced.

470 We should expect that the upscaled model will not perform well when the width of the  
471 dominant structural features is significantly larger than the model resolution scale. It should  
472 be noted that the scale separation needed for flow-based upscaling is not strictly fulfilled for  
473 the example surfaces. This is true even for the FMM case that consists of smaller wavelength  
474 structures, despite our finding that the upscaling works relatively well in that case. Our  
475 methodology would be better for upscaling sub-grid effects, i.e. only the wavelengths shorter  
476 than the 400 m grid resolution used in upscaled simulations. However, our aim was to see  
477 if upscaling the larger wavelengths could be applied for the given examples. Ultimately, the  
478 upscaling is better suited for much larger storage systems, such as the large-scale aquifers  
479 in the North Sea [24], where the subscale wavelengths are known and can be upscaled in a  
480 step-wise manner for each coarsened gridblock.

481 An alternative to upscaling is to simply coarsen the domain without employing upscaled  
482 relative permeabilities. In the OSS case, grid coarsening without upscaling would likely  
483 produce a sufficiently accurate solution. This has been demonstrated in previous work [9],  
484 which shows that coarsening the grid from 100 m to 400 m still provides sufficient resolution  
485 for the OSS case. If the surface is such that grid coarsening is inaccurate, it is also possible  
486 to consider a different approach to upscaling only the smaller wavelength features of the  
487 surface. In the FMM case, upscaling seems to be a sufficient approach since the width of  
488 the features is generally smaller than the upscaled grid block. Grid coarsening would be  
489 inappropriate for the FMM and lead to smoothing of the small features and underestimation  
490 of the topographical impact [9].

## 491 7. Summary and Conclusions

492 The key requirement of CO<sub>2</sub> storage simulations is the ability to perform large-scale  
493 simulations which describe the main physics of the plume over multiple length and time

494 scales. We have focused on structural heterogeneity and its impact on plume migration and  
495 trapping in this paper. This modeling process may require upscaling of fine-scale geological  
496 features, for which all the details may not be known or observable. Hence, it is important  
497 to determine the detailed information that is necessary to get to correct upscaled behavior.  
498 We identified some of the main parameters of the top surface topography which govern the  
499 plume migration. In particular, we show how these parameters affect the upscaled relative  
500 permeability functions. Subsequently, we discussed the effect of the parameters in the context  
501 of full field simulations on two different topographical cases. And finally, we discussed how  
502 the effects of the top surface structure interact with the main physical forces in a VE setting,  
503 which include surface tilting and strength of capillary forces, for the given cases.

504 We investigated the use of flow-based upscaling for performing direct numerical simula-  
505 tions and investigating flow characteristics of real field models. The main findings of the  
506 paper is a set of parameter groupings, which can be easily found for a surface and give infor-  
507 mation about trapping volume, sensitivity to tilt angle and flow characteristics of a plume.  
508 These parameters are valuable for deciding on a simulation strategy that introduces subscale  
509 features into a large-scale simulation. In particular, we have shown that the most important  
510 features that must be captured are as follows, with decreasing order of importance:

- 511 • amount of trapped CO<sub>2</sub>, which impacts the point at which CO<sub>2</sub> begins to flow freely;
- 512 and
- 513 • the features that affect CO<sub>2</sub> flow at the start of the flowing regime.

514 While the dimensionless groupings are an important result of this work and give insight  
515 into how CO<sub>2</sub> flow will be impacted for a given caprock surface, we emphasize that the  
516 dimensional analysis should be accompanied by simulation studies on the upscaled model.  
517 In addition, the utility of the groupings should be further explored for a greater variety of  
518 geologic models.

519 We have shown that the best approach for long-term storage capacity or storage security  
520 simulations can be guided by an evaluation of the dominant structural characteristics. In  
521 particular, expensive grid refinement often associated with large-scale simulation can be

522 avoided by the proper choice of upscaling or grid coarsening. These results also give insight  
523 into how a complex geological model can be simplified. For example, we have shown that  
524 detailed knowledge of the surface is only needed in locations where the plume thickness  
525 is small, which will occur mainly near the edges of the migrating plume. Through model  
526 simplification using appropriate techniques, large-scale CO<sub>2</sub> simulation can be performed  
527 more efficiently and effectively for real storage systems.
